Roadmap

1 Embedding Numerous Features: Kernel Models

Lecture 6: Support Vector Regression

kernel ridge regression (dense) via ridge regression + **representer theorem**;
support vector regression (sparse) via regularized **tube** error + **Lagrange dual**

2 Combining Predictive Features: Aggregation Models

Lecture 7: Blending and Bagging

- Motivation of Aggregation
- Uniform Blending
- Linear and Any Blending
- Bagging (Bootstrap Aggregation)

3 Distilling Implicit Features: Extraction Models

An Aggregation Story

Your T friends g_1, \dots, g_T predicts whether stock will go up as $g_t(\mathbf{x})$.

You can ...

- **select** the most trust-worthy friend from their **usual performance**
—**validation!**
- **mix** the predictions from all your friends **uniformly**
—let them **vote!**
- **mix** the predictions from all your friends **non-uniformly**
—let them **vote**, but **give some more ballots**
- **combine** the predictions **conditionally**
—if [**t satisfies some condition**] give some ballots to friend t
- ...

aggregation models: **mix** or **combine**
hypotheses (for better performance)

Agregation with Math Notations

Your T friends g_1, \dots, g_T predicts whether stock will go up as $g_t(\mathbf{x})$.

- **select** the most trust-worthy friend from their **usual performance**

$$G(\mathbf{x}) = g_{t_*}(\mathbf{x}) \text{ with } t_* = \operatorname{argmin}_{t \in \{1, 2, \dots, T\}} E_{\text{val}}(g_t^-)$$

在一個比較小的
g-set所得到的
validation error

- **mix** the predictions from all your friends **uniformly**

$$G(\mathbf{x}) = \operatorname{sign}\left(\sum_{t=1}^T \mathbf{1} \cdot g_t(\mathbf{x})\right)$$

- **mix** the predictions from all your friends **non-uniformly**

$$G(\mathbf{x}) = \operatorname{sign}\left(\sum_{t=1}^T \alpha_t \cdot g_t(\mathbf{x})\right) \text{ with } \alpha_t \geq 0$$

- include **select**: $\alpha_t = [\![E_{\text{val}}(g_t^-) \text{ smallest}]\!]$ 只給最值得信任的人一票而已
- include **uniformly**: $\alpha_t = 1$ 每個人票的權重都一樣

- **combine** the predictions **conditionally**

$$G(\mathbf{x}) = \operatorname{sign}\left(\sum_{t=1}^T q_t(\mathbf{x}) \cdot g_t(\mathbf{x})\right) \text{ with } q_t(\mathbf{x}) \geq 0$$

- include **non-uniformly**: $q_t(\mathbf{x}) = \alpha_t$

aggregation models: a **rich family**

Recall: Selection by Validation

$$G(\mathbf{x}) = g_{t_*}(\mathbf{x}) \text{ with } t_* = \operatorname{argmin}_{t \in \{1, 2, \dots, T\}} E_{\text{val}}(g_t^-)$$

- **simple** and popular
- what if use $E_{\text{in}}(g_t)$ instead of $E_{\text{val}}(g_t^-)$?
complexity price on d_{VC} , remember? :-)
- need **one strong** g_t^- to guarantee small E_{val} (and small E_{out})

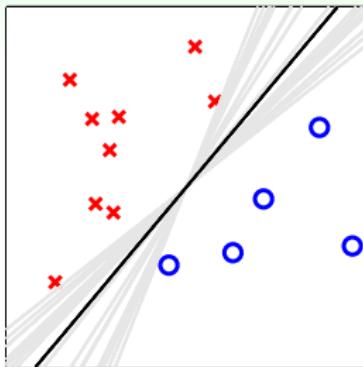

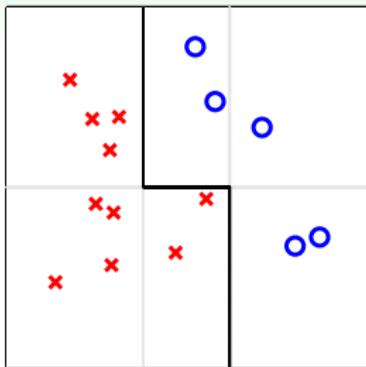

selection:

rely on one strong hypothesis

aggregation:

can we do better with many
(possibly weaker) hypotheses?

Why Might Aggregation Work?

- mix **different weak hypotheses** uniformly
— $G(\mathbf{x})$ ‘strong’
- aggregation
 \implies **feature transform (?)**

- mix **different random-PLA hypotheses** uniformly
— $G(\mathbf{x})$ ‘moderate’
- aggregation
 \implies **regularization (?)**

投票這個行為似乎同時具有上述兩個效果！？

proper aggregation \implies better performance

Fun Time

Consider three decision stump hypotheses from \mathbb{R} to $\{-1, +1\}$:
 $g_1(x) = \text{sign}(1 - x)$, $g_2(x) = \text{sign}(1 + x)$, $g_3(x) = -1$. When mixing
the three hypotheses uniformly, what is the resulting $G(x)$?

- ① $2 \llbracket |x| \leq 1 \rrbracket - 1$
- ② $2 \llbracket |x| \geq 1 \rrbracket - 1$
- ③ $2 \llbracket x \leq -1 \rrbracket - 1$
- ④ $2 \llbracket x \geq +1 \rrbracket - 1$

Fun Time

Consider three decision stump hypotheses from \mathbb{R} to $\{-1, +1\}$:
 $g_1(x) = \text{sign}(1 - x)$, $g_2(x) = \text{sign}(1 + x)$, $g_3(x) = -1$. When mixing
the three hypotheses uniformly, what is the resulting $G(x)$?

- ① $2 \llbracket |x| \leq 1 \rrbracket - 1$
- ② $2 \llbracket |x| \geq 1 \rrbracket - 1$
- ③ $2 \llbracket x \leq -1 \rrbracket - 1$
- ④ $2 \llbracket x \geq +1 \rrbracket - 1$

Reference Answer: ①

The ‘region’ that gets two positive votes
from g_1 and g_2 is $|x| \leq 1$, and thus $G(x)$ is
positive within the region only. We see that the
three decision stumps g_t can be aggregated to
form a more sophisticated hypothesis G .

Uniform Blending (Voting) for Classification

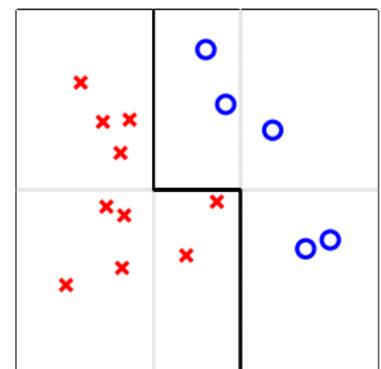

uniform blending: known g_t , each with 1 ballot

$$G(\mathbf{x}) = \text{sign} \left(\sum_{t=1}^T \mathbf{1} \cdot g_t(\mathbf{x}) \right)$$

- same g_t (autocracy):
as good as one single g_t
- very different g_t (diversity + democracy):
majority can correct minority
- similar results with uniform voting for
multiclass

$$G(\mathbf{x}) = \underset{1 \leq k \leq K}{\operatorname{argmax}} \sum_{t=1}^T \llbracket g_t(\mathbf{x}) = k \rrbracket$$

對於每個類別 k 統計各得幾票、並選出得票數最高的那個類別

how about regression?

Uniform Blending for Regression

$$G(\mathbf{x}) = \frac{1}{T} \sum_{t=1}^T g_t(\mathbf{x})$$

預測夾起來取平均 (for regression)

- same g_t (autocracy):
as good as one single g_t
- very different g_t (**diversity + democracy**):
some $g_t(\mathbf{x}) > f(\mathbf{x})$, some $g_t(\mathbf{x}) < f(\mathbf{x})$
 \Rightarrow average **could be** more accurate than individual

diverse hypotheses:

even simple **uniform blending**
can be better than any **single hypothesis**

Theoretical Analysis of Uniform Blending

概要地說明為什麼uniform blending會表現得比較好？

$$G(\mathbf{x}) = \frac{1}{T} \sum_{t=1}^T g_t(\mathbf{x})$$

$$\begin{aligned}
 \text{avg} ((g_t(\mathbf{x}) - f(\mathbf{x}))^2) &= \text{avg} (g_t^2 - 2g_t f + f^2) \\
 \text{這邊是對單點 } \mathbf{x} \text{ 做計算} &= \text{avg} (g_t^2) - 2Gf + f^2 \\
 &= \text{avg} (g_t^2) - G^2 + (G - f)^2 \\
 &= \text{avg} (g_t^2) - 2G^2 + G^2 + (G - f)^2 \\
 &= \text{avg} (g_t^2 - 2g_t G + G^2) + (G - f)^2 \\
 &= \text{avg} ((g_t - G)^2) + (G - f)^2
 \end{aligned}$$

$$\begin{aligned}
 \text{avg} (E_{\text{out}}(g_t)) &= \text{avg} (\mathcal{E}(g_t - G)^2) + E_{\text{out}}(G) \\
 \text{這邊是做所有點的expectation} &\geq + E_{\text{out}}(G)
 \end{aligned}$$

Some Special g_t

consider a **virtual** iterative process that for $t = 1, 2, \dots, T$

- ① request size- N data \mathcal{D}_t from P^N (i.i.d.)
- ② obtain g_t by $\mathcal{A}(\mathcal{D}_t)$

$$\bar{g} = \lim_{T \rightarrow \infty} G = \lim_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T g_t = \mathcal{E}_{\mathcal{D}} \mathcal{A}(\mathcal{D})$$

$$\text{avg}(E_{\text{out}}(g_t)) = \text{avg}(\mathcal{E}(g_t - \bar{g})^2) + E_{\text{out}}(\bar{g})$$

expected performance of \mathcal{A} = **expected deviation to consensus**
 演算法表現的期望值
 + performance of consensus

bias and variance decomposition

- performance of **consensus**: called **bias** 這些共識離我想要的表現差多遠
- **expected deviation to consensus**: called **variance**

uniform blending:

reduces **variance** for more stable performance

Consider applying uniform blending $G(\mathbf{x}) = \frac{1}{T} \sum_{t=1}^T g_t(\mathbf{x})$ on linear regression hypotheses $g_t(\mathbf{x}) = \text{innerprod}(\mathbf{w}_t, \mathbf{x})$. Which of the following property best describes the resulting $G(\mathbf{x})$?

- 1 a constant function of \mathbf{x}
- 2 a linear function of \mathbf{x}
- 3 a quadratic function of \mathbf{x}
- 4 none of the other choices

Consider applying uniform blending $G(\mathbf{x}) = \frac{1}{T} \sum_{t=1}^T g_t(\mathbf{x})$ on linear regression hypotheses $g_t(\mathbf{x}) = \text{innerprod}(\mathbf{w}_t, \mathbf{x})$. Which of the following property best describes the resulting $G(\mathbf{x})$?

- ① a constant function of \mathbf{x}
- ② a linear function of \mathbf{x}
- ③ a quadratic function of \mathbf{x}
- ④ none of the other choices

Reference Answer: ②

$$G(\mathbf{x}) = \text{innerprod} \left(\frac{1}{T} \sum_{t=1}^T \mathbf{w}_t, \mathbf{x} \right)$$

which is clearly a linear function of \mathbf{x} . Note that we write ‘innerprod’ instead of the usual ‘transpose’ notation to avoid symbol conflict with T (number of hypotheses).

Linear Blending

linear blending: known g_t , each to be given α_t ballot

$$G(\mathbf{x}) = \text{sign}\left(\sum_{t=1}^T \alpha_t \cdot g_t(\mathbf{x})\right) \text{ with } \alpha_t \geq 0$$

computing ‘good’ α_t : $\min_{\alpha_t \geq 0} E_{\text{in}}(\alpha)$

linear blending for regression

$$\min_{\alpha_t \geq 0} \frac{1}{N} \sum_{n=1}^N \left(y_n - \sum_{t=1}^T \alpha_t g_t(\mathbf{x}_n) \right)^2$$

LinReg + transformation

$$\min_{\mathbf{w}_i} \frac{1}{N} \sum_{n=1}^N \left(y_n - \sum_{i=1}^{\tilde{d}} \mathbf{w}_i \phi_i(\mathbf{x}_n) \right)^2$$

like two-level learning, remember? :-)

多了\alpha >= 0

linear blending = LinModel + hypotheses as transform + constraints

Constraint on α_t

linear blending = LinModel + hypotheses as transform + constraints:

$$\min_{\alpha_t \geq 0} \quad \frac{1}{N} \sum_{n=1}^N \text{err} \left(y_n, \sum_{t=1}^T \alpha_t g_t(\mathbf{x}_n) \right)$$

linear blending for binary classification

但事實上我們可以把那個constraint拿掉

$$\text{if } \alpha_t < 0 \implies \alpha_t g_t(\mathbf{x}) = |\alpha_t| (-g_t(\mathbf{x}))$$

- negative α_t for $g_t \equiv$ positive $|\alpha_t|$ for $-g_t$
- if you have a stock up/down classifier with 99% error, tell me!
:-)

in practice, often

linear blending = LinModel + hypotheses as transform ~~+ constraints~~

Linear Blending versus Selection

in practice, often

$$g_1 \in \mathcal{H}_1, g_2 \in \mathcal{H}_2, \dots, g_T \in \mathcal{H}_T$$

by minimum E_{in}

- recall: selection by minimum E_{in}
 - best of best, paying $d_{\text{VC}} \left(\bigcup_{t=1}^T \mathcal{H}_t \right)$
- recall: linear blending includes selection as special case
 - by setting $\alpha_t = [\![E_{\text{val}}(g_t^-)]\!]_{\text{smallest}}$
- complexity price of linear blending with E_{in} (aggregation of best):

$$\geq d_{\text{VC}} \left(\bigcup_{t=1}^T \mathcal{H}_t \right)$$

like selection, blending practically done with
 $(E_{\text{val}} \text{ instead of } E_{\text{in}}) + (g_t^- \text{ from minimum } E_{\text{train}})$

演算法之所以可以那樣做的
原因，是因為前面我們推
倒發現，其實跟那個兩階
段learing是等價的

演算法（以linear為例）：

1. 從D_train用linear得到\alpha跟g_1
2. 把D_val透過前面的g_1轉換到\phi中的z空間
3. 用這個z空間再對y跑linear model得到最終的\alpha

Any Blending

Given $g_1^-, g_2^-, \dots, g_T^-$ from $\mathcal{D}_{\text{train}}$, transform (x_n, y_n) in \mathcal{D}_{val} to
 $(z_n = \Phi^-(x_n), y_n)$, where $\Phi^-(x) = (g_1^-(x), \dots, g_T^-(x))$

Linear Blending

- 1 compute α

$$= \text{LinearModel}\left(\{(z_n, y_n)\}\right)$$

- 2 return $G_{\text{LINB}}(x) =$

LinearHypothesis $_\alpha(\Phi(x))$,

Any Blending (**Stacking**)

- 1 compute \tilde{g}

$$= \text{AnyModel}\left(\{(z_n, y_n)\}\right)$$

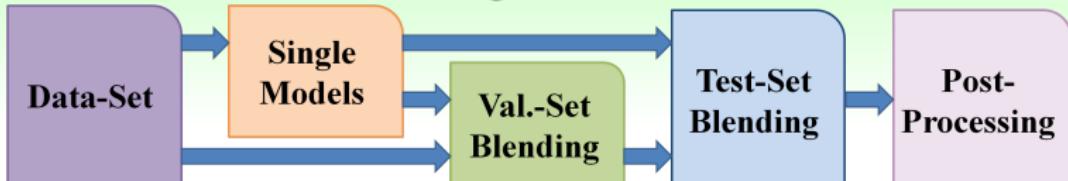

- 2 return $G_{\text{ANYB}}(x) = \tilde{g}(\Phi(x))$,

where $\Phi(x) = (g_1(x), \dots, g_T(x))$

any blending:

- **powerful**, achieves conditional blending
- but **danger of overfitting**, as always :-(

Blending in Practice

(Chen et al., A linear ensemble of individual and blended models for music rating prediction, 2012)

KDDCup 2011 Track 1: World Champion Solution by NTU

- validation set blending: a special any blending model

$$E_{\text{test}} \text{ (squared): } 519.45 \implies 456.24$$

—helped **secure the lead** in last two weeks

- test set blending: linear blending using \tilde{E}_{test}

$$E_{\text{test}} \text{ (squared): } 456.24 \implies 442.06$$

—helped **turn the tables** in last hour

blending ‘useful’ in practice,
despite the computational burden

Fun Time

Consider three decision stump hypotheses from \mathbb{R} to $\{-1, +1\}$:

$g_1(x) = \text{sign}(1 - x)$, $g_2(x) = \text{sign}(1 + x)$, $g_3(x) = -1$. When $x = 0$, what is the resulting $\Phi(x) = (g_1(x), g_2(x), g_3(x))$ used in the returned hypothesis of linear/any blending?

- ① (+1, +1, +1)
- ② (+1, +1, -1)
- ③ (+1, -1, -1)
- ④ (-1, -1, -1)

Fun Time

Consider three decision stump hypotheses from \mathbb{R} to $\{-1, +1\}$:

$g_1(x) = \text{sign}(1 - x)$, $g_2(x) = \text{sign}(1 + x)$, $g_3(x) = -1$. When $x = 0$, what is the resulting $\Phi(x) = (g_1(x), g_2(x), g_3(x))$ used in the returned hypothesis of linear/any blending?

- ① (+1, +1, +1)
- ② (+1, +1, -1)
- ③ (+1, -1, -1)
- ④ (-1, -1, -1)

Reference Answer: ②

Too easy? :-)

What We Have Done

blending: aggregate **after getting g_t** ;

learning: aggregate **as well as getting g_t**

aggregation type	blending	learning
uniform	voting/averaging	?
non-uniform	linear	?
conditional	stacking	?

learning g_t for uniform aggregation: **diversity** important

- **diversity** by different models: $g_1 \in \mathcal{H}_1, g_2 \in \mathcal{H}_2, \dots, g_T \in \mathcal{H}_T$
- **diversity** by different parameters: GD with $\eta = 0.001, 0.01, \dots, 10$
- **diversity** by algorithmic randomness:
random PLA with different random seeds
- **diversity** by data randomness:
within-cross-validation hypotheses g_v^-

next: **diversity** by data randomness **without g^-**

Revisit of Bias-Variance

$$\begin{aligned}\text{expected performance of } \mathcal{A} &= \text{expected deviation to consensus} \\ &\quad + \text{performance of consensus} \\ \text{consensus } \bar{g} &= \text{expected } g_t \text{ from } \mathcal{D}_t \sim P^N\end{aligned}$$

- **consensus** more stable than direct $\mathcal{A}(\mathcal{D})$,
but comes from many more \mathcal{D}_t than the \mathcal{D} on hand
- want: approximate \bar{g} by
 - finite (large) T
 - approximate $g_t = \mathcal{A}(\mathcal{D}_t)$ from $\mathcal{D}_t \sim P^N$ using only \mathcal{D}

bootstrapping: a statistical tool that
re-samples from \mathcal{D} to 'simulate' \mathcal{D}_t

Bootstrap Aggregation

bootstrapping

bootstrap sample $\tilde{\mathcal{D}}_t$: re-sample N examples from \mathcal{D} **uniformly with replacement**—can also use arbitrary N' instead of original N

virtual aggregation

consider a **virtual** iterative process that for $t = 1, 2, \dots, T$

- ① request size- N data \mathcal{D}_t from P^N (i.i.d.)
- ② obtain g_t by $\mathcal{A}(\mathcal{D}_t)$
 $G = \text{Uniform}(\{g_t\})$

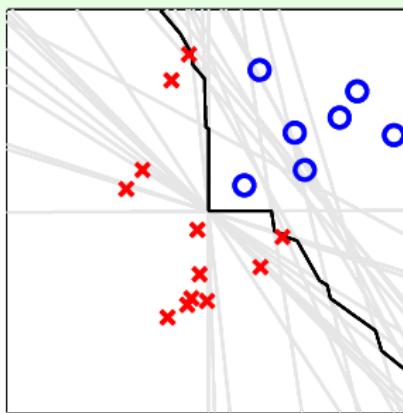

bootstrap aggregation

consider a **physical** iterative process that for $t = 1, 2, \dots, T$

- ① request size- N' data $\tilde{\mathcal{D}}_t$ from bootstrapping
- ② obtain g_t by $\mathcal{A}(\tilde{\mathcal{D}}_t)$
 $G = \text{Uniform}(\{g_t\})$

bootstrap aggregation (BAGging):
 a simple **meta algorithm**
 on top of **base algorithm** \mathcal{A}

Bagging Pocket in Action

$$T_{\text{POCKET}} = 1000; T_{\text{BAG}} = 25$$

- very diverse g_t from bagging
- proper **non-linear** boundary after aggregating binary classifiers

前面我們有提到我們想要 g 擁有一些diversity，也就是我們不想要所有的 g 都長一樣，這樣子blending就沒有意義。所以透過bagging，我們可以讓這些 g 增加一點隨機性、進而產生一些diversity，如此一來投票的效果才比較好。

bagging works reasonably well if base algorithm sensitive to data randomness

Fun Time

When using bootstrapping to re-sample N examples $\tilde{\mathcal{D}}_t$ from a data set \mathcal{D} with N examples, what is the probability of getting $\tilde{\mathcal{D}}_t$ exactly the same as \mathcal{D} ?

- 1 $0 / N^N = 0$
- 2 $1 / N^N$
- 3 $N! / N^N$
- 4 $N^N / N^N = 1$

Fun Time

When using bootstrapping to re-sample N examples $\tilde{\mathcal{D}}_t$ from a data set \mathcal{D} with N examples, what is the probability of getting $\tilde{\mathcal{D}}_t$ exactly the same as \mathcal{D} ?

- 1 0 $/N^N = 0$
- 2 1 $/N^N$
- 3 $N! /N^N$
- 4 $N^N /N^N = 1$

Reference Answer: ③

Consider re-sampling in an ordered manner for N steps. Then there are (N^N) possible outcomes $\tilde{\mathcal{D}}_t$, each with equal probability. Most importantly, $(N!)$ of the outcomes are permutations of the original \mathcal{D} , and thus the answer.

Summary

- ① Embedding Numerous Features: Kernel Models
- ② Combining Predictive Features: Aggregation Models

Lecture 7: Blending and Bagging

- Motivation of Aggregation
aggregated G strong and/or moderate
 - Uniform Blending
diverse hypotheses, ‘one vote, one value’
 - Linear and Any Blending
two-level learning with hypotheses as transform
 - Bagging (Bootstrap Aggregation)
bootstrapping for diverse hypotheses
-
- **next: getting more diverse hypotheses to make G strong**
- ③ Distilling Implicit Features: Extraction Models
